**Method and means for allocating time slots in a TDD system**

The present invention relates to a method and a means for allocating time slots in a time division duplex communication system. Particularly, the method and the means for allocating time slots according to the present invention can be implemented in communication units of a time division duplex communication system, e. g. a base station and/or a mobile station of a telecommunication system.

In a time division duplex communication system, examples of which are the GSM-standard for outdoor mobile communication or the DECT-standard for indoor mobile telephone communication, the receiving and the transmitting channels are separated on a time basis. E. g. in the DECT-standard, the information is transmitted in time frames of a length of 10 ms having 24 time slots. The first 12 time slots are used for the downlink connection, that is the transmission of data from a base station to a mobile station. The last 12 time slots are used for the uplink connection, that is for the transmission of data from a mobile station to the base station. In the GSM-standard, a combination of a frequency division duplex and a time division duplex is used. The information is transmitted in time frames having 8 time slots, whereby the uplink connection is provided in a lower frequency band and the downlink connection is provided in a higher frequency band. Each of the 8 time slots in each frame is assigned to a different mobile station. Thereby, the time slots assigned to a certain mobile station within a downlink time frame are separated from the time slots assigned to the same mobile station in the uplink time frame by two time slots. In other words, if e. g. the first time slot in a downlink time frame is assigned to a certain mobile station, the fourth time slot in an uplink time frame is assigned to the same mobile station. The time basis separation of the uplink and downlink time slots enables the construction of the mobile stations to be made more simple, since the reception and the transmission of data does not take place simultaneously.

Since in telecommunication systems as e. g. the GSM-system the data transfer rate is restricted, attempts have been made to increase the data transfer rate by allocating more than one time slot per frame to a certain mobile station. In JP 05153033-A such a TD digital mobile telecommunication system is disclosed, in which the same frequency for transmitting and receiving information is used. 1 to N time slots within one uplink time frame are allocated to one mobile station and 1 to N time slots within one downlink

time frame are allocated to one mobile station depending on the information volume to be transferred between the mobile station and a base station. Each frame is allocated either to the uplink transfer of data or the downlink transfer of data. The uplink time frames cannot be used for a downlink transfer of data, so that a strong asymmetric transmission of information with a large difference between the amount of uplink data and the amount of downlink data is not possible.

In JP 07107546-A, a TDMA radio communication system is disclosed, in which the ratio between the number of uplink and downlink time slots within one time frame or one super frame consisting of several time frames is changed according to the total amount of traffic between a base station and mobile stations. In case of fast changing data transfer amounts, the switching point within each frame between the uplink time slots and the downlink time slots often changes position. Every change of such a switching point requires a reallocation of several time slots for the different connected mobile stations. This known system therefore requires a complicated circuitry.

The slot allocation method disclosed in EP 654916-A2 suffers from the same problems.

The object of the present invention is therefore to provide a method and means for allocating time slots in a time division duplex communication system, which allow a simple and efficient time slot allocation for varying transfer information amounts.

This object is achieved by a method for allocating time slots according to claim 1 and a means for allocating time slots according to claim 8. Advantageous features of the present invention are defined in the respective subclaims.

According to claim 1, the present invention relates to a method for allocating time slots in a time division duplex communication system, in which the information is transmitted in predetermined time frames having a predetermined number of time slots. In a GSM-system, the number of time slots per time frame is 8. Each time frame comprises a fixed block of one receiving time slot and one transmitting time slot being adjacent to each other. In case that the method according to the present invention is implemented in a communication unit as e. g. a mobile station, the receiving time slot is a downlink time slot and the transmitting time slot is an uplink time slot. The method for allocating time slots according to the present invention comprises the step of allocating at least the time slot adjacent to the receiving time slot as additional receiving time slot and at least the time slot adjacent to the transmitting time slot as additional transmitting time slot dependent on an amount of information to be transferred.

Thus, starting from the fixed block consisting of the receiving and the transmitting time slot, the time slots for receiving and transmitting are extended, whereby additional receiving time slots are added on the side of the receiving time slot of the fixed block and additional transmitting time slots are added on the side of the transmitting time slot of the fixed block. Thereby, the additional time slots can be added or additionally allocated crossing the border of two adjacent time frames. In other words, the additional time slots can be extended from one time frame into an adjacent time frame.

Thus, even if a big difference between the uplink data amount and the downlink data amount occurs, the method and the means according to the present invention provides an efficient and simple possibility to transfer the information to be transferred asymmetrically. Since the position of the switching point between the receiving time slot and the transmitting time slot is fixed due to the fixed block position, the method according to the present invention allows a transfer data amount change of a certain mobile station without the need of a reallocation of time slots for other mobile stations. Thus, the present invention is particularly advantageous in a multiple access communication system, in which one time frame is assigned to several communication units, e. g. several mobile stations.

Advantageously, the number of additional receiving time slots and the number of additional transmitting time slots are independent from each other. This means, that data or information can be transferred asymmetrically between two communication units. The receiving and the transmitting time slot of the fixed block can be allocated to a common first communication unit, e. g. a mobile station, whereby the transmitting time slot precedes the or is earlier than the receiving time slot. In other words, the transmitting time slot is positioned in front of the receiving time slot on the time axis, so that problems in view of the timing advance can be provided. The timing advance means, that the base station has to receive an uplink time slot at a correct timing. To meet this requirement, the transmission timing of the uplink time slot is adjusted e. g. by a mobile station taking the propagation delay into consideration. Of course, the propagation delay is more important in outdoor environments, in which communication units as e. g. mobile stations are sometimes moved with high speed or in which multipath effects occur. The adjustment of the transmission timing of the uplink time slot is called timing advance. Here is the method of the present invention is implemented in a mobile station and if the transmitting time slot is earlier than the receiving time slot, the transmission timing of the uplink time slot transmitted from the mobile station to the station is not necessary, since the timing advance does not play a role in this case.

The additional time slots can either be allocated to the same first communication unit as the fixed block, or, in case of a multiple access communication system, one time frame is assigned to several communication units and the additional time slots are allocated to communication units different from said first communication unit. Even in a multiple  
5 access communication system, the present invention provides an advantageous possibility for an asymmetric data transfer.

The above-mentioned timing advance only becomes important, if all the time slots of a time frame are used for data transfer. Even in case that the transmitting time slot is  
10 preceding the receiving time slot, in one position of the time frame another switching point between a transmitting time slot and a receiving time slot occurs. In this switching point, a receiving time slot is preceding a transmitting time slot, so that, e. g. in a mobile station, the timing advance leads to a possible overlap of the earlier receiving time slot into the later transmitting time slot. In this case, a guard period can be  
15 provided in at least one of the adjacent time slots. In other words, a guard period can be provided either in the earlier receiving time slot or in the later transmitting time slot to avoid problems due to the timing advance. Advantageously, the guard period is only provided at the end of the receiving time slot.

20 According to claim 8, a means for allocating time slots in a time division duplex communication system is provided, in which the information is transmitted in predetermined time frames having a predetermined number of time slots. Each time frame comprises a fixed block of one receiving time slot and one transmitting time slot being adjacent to each other. Said means for allocating time slots allocates at least the  
25 time slot adjacent to the receiving time slot as additional receiving time slot and at least the time slot adjacent to the transmitting time slot as additional transmitting time slot dependent on an amount of information to be transferred. Said means for allocating time slots according to the present invention can e. g. be implemented in a communication unit of a telecommunication system, as a mobile station and/or a base  
30 station. All statements above made in reference to the method for allocating time slots according to the present invention are identically true for the means for allocating time slots according to the present invention.

In the following description, preferred embodiments of the present invention are  
35 explained relating to the accompanying drawings, in which

figure 1 shows an example of a fixed block comprising one receiving time slot and one transmitting time slot being located at the beginning of respective time frames,

figure 2 shows some time frames with additional transmitting time slots and additional receiving time slots,

figure 3 shows some other time frames, wherein one of the time frames is saturated with data to be transmitted or received, so that an additional switching point is present.

figure 4 shows an enlarged section of figure 3 showing a timing advance of an additional transmitting time slot adjacent to a preceding receiving time slot, and

figure 5 shows a schematic example of a communication unit comprising a means for allocating time slots according to the present invention.

In figure 1, three time frames  $F_1$ ,  $F_2$  and  $F_3$  are schematically shown. Each frame contains e. g. eight time slots, as in a GSM-system. Although all time frames shown in figure 1, 2 and 3 comprise eight time slots, the present invention is not limited to this case and the time frames can comprise any other required number of time slots. In each frame, the first two time slots 1 and 2 build a fixed block comprising a transmitting time slot 1 and a receiving time slot 2. In case that the present invention is implemented e. g. in a mobile station of a telecommunication system, the transmitting time slot is an uplink time slot for transmitting data or information from the mobile station to a base station, and the receiving time slot 2 is a downlink time slot for transmitting data from the base station to the mobile station. The transmitting time slot 1 and the receiving time slot 2 are thus assigned to a certain pair of communication units, e. g. a base station and a mobile station. The base station can thereby be part of the multiple access communication system, in which one frame is assigned to several mobile stations. The fixed block comprising the transmitting time slot 1 and the receiving time slot 2, however, is always on a fixed position.

In the first and second frame  $F_1$  and  $F_2$  shown in figure 1, the six remaining time slots 3 to 8 in each frame are not used for transferring information. Since the transmitting time slot 1 is placed in advance of the receiving time slot 2, this slot allocation can cope with timing advance as explained above. For a base station, the timing advance is adjusted by adjusting the timing of the time slots transmitted from the base station to the mobile station.

In the example shown in figure 1, the first frame  $F_1$ , the next frame  $F_2$  and the third frame  $F_3$  are not saturated since only the transmitting time slot 1 and the transmitting time slot 2 of the fixed block are used to transfer information in each of the frames.

The last time slot 8 of the third frame  $F_3$  is an additional transmitting time slot of the fixed block of the fourth frame  $F_4$  of figure 4.

In figure 2, information are transmitted in the transmitting time slot 1 and the receiving time slot 2 forming a fixed block in each of the shown frames  $F_4$ ,  $F_5$  and  $F_6$ , as in the first example shown in figure 1. However, since there is more information to send and to receive, an additional transmitting time slot 8 is added before the time slot 1 of the fixed block in the time axis direction. Additional receiving time slots 3 and 4 are added behind the receiving time slot 2 in the time axis direction. Thus, an increased amount of information or data can be transferred between a mobile station and a base station or between several mobile stations and one base station. In the later case, the additional transmitting and/or receiving time slots can be allocated to different mobile stations. For example in the fifth time frame  $F_5$ , the additional receiving time slots 3, 4, 5 can be allocated to one or more different mobile stations. The position of the basic block, however, remains unchanged, so that the switching point between transmitting and receiving information, which is located between the first time slot 1 and the second time slot 2 in each frame, remains on the same position. This switching point is the only switching point, since the time frames are not saturated with information to be transferred. As can be seen from figure 2, according to the present invention, the number of additional transmitting time slots and additional receiving time slots can be increased independently, so that an asymmetric transmission of data is possible. In case of a multiple access communication system, in which one time frame is assigned to several mobile stations, the additional time slots can be allocated to one or more different mobile stations. For a certain mobile station, the time slots to be transmitted or received may not come in a regular interval. However, the pattern of the slot allocation is maintained and continued over at least several frames, e. g. two frames  $F_1$  and  $F_2$  as shown in figure 1. In figure 2, the slot allocation pattern changes for the succeeding frames  $F_4$ ,  $F_5$  and  $F_6$ . The pattern of the slot allocation is advantageously not changed frame by frame, but is changed only, when the required data amount to be transferred is changed. This is the case for the time frame shown in figure 2, in which the data amount to be transferred is reduced to one transmitting time slot from frame  $F_4$  to frame  $F_5$  and the receiving time slot 2 from frame  $F_5$  to frame  $F_6$ .

In case of a multiple access communication system, in which different time slots are assigned to different mobile stations, the time slots 3 and 4 being used as additional receiving time slots and the time slot 8 being used as additional transmitting time slot in the time frame  $F_4$  can be assigned to a second mobile station, when the transmitting time slot 1 and the receiving time slot 2 of the fixed block are assigned to a first mobile

station. The time slots 3 and 4 can also be allocated to a second mobile station and a third mobile station, respectively.

In case that the amount of information to be transferred is further increased, the maximum information transfer rate can be achieved by using all the time slots in each time frame for transferring data, as shown in figure 3 for the time frame  $F_7$ . In the shown example, the transmitting time slot 1 and the receiving time slot 2 are still on their fixed position at the beginning of each time frame. The time slots 3 to 7 of the frame  $F_7$  are used as additional receiving time slots. Thereby, the different time slots 3 to 7 can be assigned or allocated to different mobile stations. An additional transmitting time slot 8 is also used in the time frame  $F_7$ , so that the last additional receiving time slot 7 and the succeeding additional transmitting time slot 8 are adjacent to each other. If in this situation the base station is located close to the mobile station, so that the propagation delay is small, there is no serious problem. If, however, the base station is located far from the mobile station, e. g. a few kilometer, the mobile station has to transmit the transmitting time slot 8 in advance to compensate for the propagation delay. In other words, a timing advance is necessary. Therefore, the mobile station has less time to receive the last additional receiving time slot 7. This situation is shown in more detail in figure 4. Figure 4 shows a section of figure 3 with the last additional receiving time slot 7 and the additional transmitting time slot 8 of the preceding frame  $F_7$  as well as the transmitting time slot 1 of the succeeding time frame  $F_8$ . As can be seen from figure 4, the last portion of the receiving time slot 7 is emptied and used as a guard period to enable an earlier transmission of the additional transmitting time slot 8. It has to be understood, that the timing advance problem only occurs, when a receiving time slot and a succeeding transmitting time slot are adjacent to each other, which are assigned to the same mobile station. It is therefore advantageous, not to allocate successive transmitting and receiving time slots to one mobile station in this case.

In time frame  $F_8$  following time frame  $F_7$  with the maximum information transfer, the amount of information to be transferred is reduced and only the time slots 3, 4 and 5 are allocated as additional receiving time slots. In the following time frame  $F_9$ , the amount of information to be transferred is further reduced to the basic block comprising the transmitting time slot 1 and the receiving time slot 2.

35

In figure 5, a communication unit 10, in which the present invention is incorporated or implemented, is schematically shown. The communication unit 10 can e. g. be a mobile station or a base station of a mobile telecommunication system.

The communication unit 10 comprises an antenna 11, through which information modulated onto respective carrier frequencies can be transmitted and received. The communication unit 10 comprises a receiving means 12, which receives incoming information through the antenna 11 and supplies the received information to a control unit 13, in which the received information are demodulated, decoded, etc. in a known manner. The control unit 13 comprises an allocation means 15, in which the time slots of the predetermined time frames are allocated depending on the amount of information to be transferred as receiving or transmitting time slots according to the method explained above. The control unit 13 can thus also comprise a means for determining the amount of information to be transferred, i. e. received or transmitted to give corresponding information to the allocation means 15, so that the allocation means 15 correspondingly allocates the time slots as receiving or transmitting time slots depending on the amount of transfer information. The allocation means 15 of the control unit 13 allocates the time slots according to the slot allocation method explained above in relation to figures 1 to 4. Thereafter, the control unit 13 provides a transmission means 14 with corresponding information to be transmitted within the correspondingly allocated time slots by means of the antenna 11 to another communication unit. The control unit 13 can further comprise a guard period means 16, which, in case that an additional receiving time slot and an additional transmitting time slot become adjacent to each other, e. g. in the case shown in figures 3 and 4, provides a guard period in at least one of said adjacent additional time slots. As stated above, this situation becomes only relevant in the case that the preceding receiving time slot and the succeeding transmitting time slot are assigned to the same communication unit 10. In this case it is advantageous, if the guard period means 16 provides said guard period at the end of said additional receiving time slots, e. g. the additional receiving time slot 7 of time frame  $F_7$  shown in figure 3 and 4.

**Claims**

1. Method for allocating time slots in a time division duplex communication system, in which the information is transmitted in predetermined time frames (F) having a predetermined number of time slots, whereby each time frame ( $F_1, F_2, \dots$ ) comprises a fixed block of one receiving time slot (2) and one transmitting time slot (1) being adjacent to each other, comprising the step of allocating at least the time slot (3) adjacent to the receiving time slot (2) as additional receiving time slot and at least the time slot (8) adjacent the transmitting time slot (1) as additional transmitting time slot dependent on an amount of information to be transferred.

2. Method for allocating time slots according to claim 1, characterized in, that the number of additional receiving time slots and the number of additional transmitting time slots are independent from each other.

3. Method for allocating time slots according to claim 1, characterized in, that the one receiving and one transmitting time slot (2, 1) of the fixed block are allocated to a first communication unit (10), whereby the transmitting time slot (1) is preceding the receiving time slot (2).

4. Method for allocating time slots according to claim 3, characterized in, that the additional slots are also allocated to the first communication unit (10).

5. Method for allocating time slots according to one of the claims 1 to 3, characterized in, that one of time frame ( $F_1, F_2, \dots$ ) is assigned to several communication units and the additional time slots are allocated to communication units different from said first communication unit (10).

6. Method for allocating time slots according to one of the preceding claims, characterized in,

that in case that an additional time slot (7) of a preceding fixed block and an additional time slot (8) of a succeeding fixed block are adjacent to each other, a guard period (17) is provided in at least one of said adjacent additional time slots.

- 5     7. Method for allocating time slots according to claim 6,  
characterized in,

that said additional time slot (7) of said preceding fixed block is a receiving time slot and said additional time slot (8) of said succeeding fixed block is a transmitting time slot, whereby said guard period (17) is provided at the end of said receiving time  
10     slot (7).

8. Means (15) for allocating time slots in a time division duplex communication system, in which the information is transmitted in predetermined time frames (F) having a predetermined number of time slots, whereby each time frame ( $F_1, F_2, \dots$ ) comprises a  
15     fixed block of one receiving time slot (2) and one transmitting time slot (1) being adjacent to each other, said means (15) allocating at least the time slot (2) adjacent to the receiving time slot as additional receiving time slot and at least the time slot (8) adjacent the transmitting time slot (1) as additional transmitting time slot dependent on an amount of information to be transferred.

20

9. Means for allocating time slots according to claim 8,  
characterized in,

that the number of additional receiving time slots and the number of additional transmitting time slots are independent from each other.

25

10. Means for allocating time slots according to claim 8 or 9,  
characterized by

allocating the one receiving and one transmitting time slot (2, 1) of the fixed block to a first communication unit, whereby the transmitting time slot (1) is preceding the  
30     receiving time slot (2).

11. Means for allocating time slots according to claim 10,  
characterized by

allocating the additional slots are also to the first communication unit (10).

35

12. Means for allocating time slots according to one of the claims 8 to 10,  
characterized in,

that one time frame ( $F_1, F_2, \dots$ ) is assigned to several communication units and the additional time slots are allocated to communication units different from said first communication unit (10).

- 5 13. Means for allocating time slots according to one of the claims 8 to 12,  
characterized by  
a guard period means (16), which, in case that an additional time slot (7) of a preceding  
fixed block and an additional time slot (8) of a succeeding fixed block are adjacent to  
each other, provides a guard period (17) in at least one of said adjacent additional time  
10 slots.
14. Means for allocating time slots according to claim 13,  
characterized in,  
that said guard period means (16), if said additional time slot (7) of said preceding fixed  
15 block is a receiving time slot and said additional time slot (8) of said succeeding fixed  
block is a transmitting time slot, provides said guard period (17) at the end of said  
receiving time slot (7).

**Abstract****Slot allocation method and means for a TDD system**

10 The present invention relates to a method and a means for allocating time slots in a time division duplex communication system, in which the information is transmitted in predetermined time frames F having a predetermined number of time slots 1 to 8. Each time frame F comprises a fixed block of one receiving time slot 2 and one transmitting time slot 1 being adjacent to each other. The means 15 for allocating the time slots allocates at least the time slot 3 adjacent to the receiving time slot as additional receiving time slot and at least the time slot adjacent to the transmitting time slot 1 as additional transmitting time slot dependent on an amount of information to be transferred. The present invention is particularly advantageous in the case of an asymmetric information transfer.
